NATIONAL AERONAUTICS AND SPACE ADMINISTRATION • WASHINGTON, D. C. • NOVEMBER 1972
The present paper summarizes the high-angle-of-attack characteristics of a number of high-performance aircraft as determined from model force tests and free-flight model tests and correlates these characteristics with the dynamic directional-stability parameter $C_{n\beta,\text{dyn}}$. This correlation shows that $C_{n\beta,\text{dyn}}$ correlates fairly well with directional divergence. Data are also presented to show the effect of some airframe modifications on the directional divergence potential of the configuration. These results show that leading-edge slats seem to be the most effective airframe modification for reducing or eliminating the directional divergence potential of aircraft with moderately swept wings.
SUMMARY OF DIRECTIONAL DIVERGENCE CHARACTERISTICS OF
SEVERAL HIGH-PERFORMANCE AIRCRAFT CONFIGURATIONS

By H. Douglas Greer
Langley Research Center

SUMMARY

Many high-performance jet airplanes have exhibited a directional divergence at angles of attack near the stall. The divergence is usually associated with aircraft having highly swept wings and can lead to large losses in altitude and spins, which can result in losses of airplanes and aircrews. A considerable amount of information has been generated by past investigations of specific airplane configurations. The present paper summarizes much of this information with special regard to the correlation of experimental data with a dynamic directional-stability parameter known as $C_{n\beta,\text{dyn}}$. Much experimental data come from free-flight dynamic model tests and wind-tunnel force tests of these same models. A limited amount of full-scale flight data is available for correlation with the model tests.

This summary shows that many, if not most, high-performance airplane configurations exhibit the directional divergence at high angles of attack. The divergence can be predicted in most cases by the criterion that when $C_{n\beta,\text{dyn}}$ is negative, a divergence will be experienced. Leading-edge slats are found to be the most effective device for eliminating the directional divergence or delaying it to higher angles of attack, at least for airplanes with wings of moderate sweep.

INTRODUCTION

Many high-performance jet aircraft have exhibited a directional divergence when flown at angles of attack near or above the stall. The directional divergence is usually associated with aircraft having highly swept or delta wings. Conditions for divergence can occur during landing approach, take-off, or in maneuvers, especially during combat maneuvers where the pilot may inadvertently cause the aircraft to reach very high angles of attack. The divergence can lead to a spin from which a recovery might or might not be obtained, or if the divergence occurs at low altitude, the likely result would be the loss of the aircraft and probably the crew.

Experience has shown that the divergence does not correlate with simple static directional stability as measured in a wind tunnel, but is a more complicated dynamic
phenomenon. A dynamic directional-stability parameter called $C_{n,\beta,dy}$, which can be determined from wind-tunnel force tests, was developed many years ago to serve as a criterion for prediction of the possibility of a directional divergence and correlates fairly well with the directional divergence characteristics shown by free-flight model tests. Considerable experience has been gained in this problem area over the past 20 years, but the results of this experience have never been summarized. The purpose of the present paper is to summarize the experience of the NASA Langley Research Center, most of it with free-flight models and wind-tunnel force tests of these same models at the same value of Reynolds number. This combination of model test techniques offers an exceptional opportunity for correlation of wind-tunnel and flight because it eliminates the two principal factors which often thwart such correlation—differences in Reynolds number and configuration.

The present paper summarizes the high-angle-of-attack characteristics of a number of high-performance aircraft as determined from model force tests and free-flight tests and correlates these characteristics with the dynamic directional-stability parameter $C_{n,\beta,dy}$. Data are also presented to show how several airframe modifications affect the static lateral-stability parameters ($C_{n,\beta}$ and $C_{l,\beta}$) and $C_{n,\beta,dy}$, and thereby offer means for altering the divergence potential of a configuration. The derivation of $C_{n,\beta,dy}$ from the lateral equations of motion is given in the appendix.

**SYMBOLS**

All aerodynamic data with the exception of lift are presented with respect to a body system of axes. The lift data are presented with respect to the wind axes (fig. 1). Dimensional values herein are given in the International System of Units (SI) (ref. 1).

- $A, B, C, D, E$: coefficients of lateral-stability quartic
- $b$: wing span, m
- $C_{L}$: lift coefficient, $\frac{\text{Lift}}{qS}$
- $C_{l}$: rolling-moment coefficient, $\frac{\text{Rolling moment}}{qSb}$
- $C_{n}$: yawing-moment coefficient, $\frac{\text{Yawing moment}}{qSb}$
- $C_{n,\beta,dy}$: directional divergence parameter, $C_{n,\beta} = \frac{I_z}{I_X} C_{l,\beta} \sin \alpha$
\[ C_R = \frac{C}{K} \]

\[ C_R' = C_{n\beta} \cos \alpha - \frac{I_Z}{I_X} C_{\beta} \sin \alpha \]

- \( C_Y \): side-force coefficient, \( \frac{\text{Side force}}{qS} \)
- \( F_D \): drag force, N
- \( F_L \): lift force, N
- \( F_Y \): side force, N
- \( I_X \): moment of inertia about longitudinal body axis, kg-m²
- \( I_Z \): moment of inertia about normal body axis, kg-m²
- \( K = \frac{4mI_X}{\rho^2S^2b^4} \)
- \( K_{X_0} \): nondimensional radius of gyration in roll about principal longitudinal axis, \( \frac{I_X}{mb^2} \)
- \( K_{Z_0} \): nondimensional radius of gyration in yaw about principal normal axis, \( \frac{I_Z}{mb^2} \)
- \( M_X \): rolling moment, m-N
- \( M_Y \): pitching moment, m-N
- \( M_Z \): yawing moment, m-N
- \( m \): aircraft mass, kg
- \( p \): rolling velocity, rad/sec
- \( q \): free-stream dynamic pressure, N/m²
Presented in figure 1 are sketches defining the axis systems and positive directions of the force and moment data are indicated.

Figure 2 presents time histories of flight data obtained from the flight recorder of a full-scale test aircraft during a directional divergence.
Data from 17 different aircraft configurations are presented. These configurations (designated A to Q) have been categorized as fighters, bombers, and transports. Included in the fighter group are research aircraft of fighter size and configuration. Plan views of the configurations are presented as follows: Fighters in figure 3; bombers in figure 4; and transports in figure 5.

Presented in figures 6 to 22 are wind-tunnel static-force test data for the configurations discussed in this paper. The force test data are presented with zero control deflection unless otherwise specified. Note that for figures 13(b), 17(b), and 19(b) the scale for $C_{n\beta,\text{dyn}}$ has been changed for convenience of plotting.

**BACKGROUND ON $C_{n\beta,\text{dyn}}$ AS A CRITERION**

In the late 1940's low-aspect-ratio swept-wing fighter configurations began to emerge, and it soon became apparent that they could behave very differently at the stall from their predecessor straight-wing configurations. Whereas straight-wing configurations generally experienced a roll-off type of divergence at the stall because of one wing stalling before the other and unstable damping in roll immediately beyond the stall, the swept-wing configurations began to show a directional divergence at high angles of attack.

In order to illustrate a directional divergence, a time history of an actual flight test of configuration J is presented in figure 2 (ref. 2). The traces presented in this figure show the major flight variables and control-surface deflections as a function of time. During the time period represented on these traces, the pilot was attempting to make a 60° banked turn to the left. After the pilot rolled into the turn, the angle of attack was increased at a fairly constant rate. At approximately 38 seconds, the normal acceleration began to decrease even though the angle of attack was still increasing, thereby indicating major stall. At approximately 50 seconds the aircraft diverged violently and entered a $2\frac{1}{2}$-turn spin to the right. This example shows not only what occurs during a divergence, but with the aircraft entering a spin, clearly illustrates the seriousness of the divergence problem.

Langley's first experience with directional divergence was encountered during tests of dynamically scaled flying models of configurations B (ref. 3) and C (ref. 4) in the Langley free-flight tunnel. From tests of these two configurations together with configuration A (ref. 5), it was apparent that the problem was more complicated than one of simple static directional instability ($C_{n}\beta$). Configurations A and B, which had similar geometric characteristics, both had negative values of $C_{n\beta}$ at high angles of attack; but configuration B diverged, whereas configuration A did not. One aerodynamic difference was that configuration A had positive dihedral effect ($-C_{l\beta}$) at high angles of attack, whereas configuration B had negative dihedral effect ($+C_{l\beta}$). Similarly, configura-
tion C diverged in the clean condition, whereas it did not diverge with slats extended, although both conditions had negative directional stability at high angles of attack. Here again the model diverged when \( C_{l\beta} \) was positive and not when \( C_{n\beta} \) was negative. The experimenting aerodynamicist quickly related these facts that a combination of \( -C_{n\beta} \) and \( +C_{l\beta} \) resulted in a directional divergence but that a combination of \( -C_{n\beta} \) and \( -C_{l\beta} \) did not. Then the dynamicist became aware of the problem and suggested that the moment of inertia differences of the old and new fighter configurations might be a contributing factor. A theoretical analysis group headed by Leonard Sternfield, then of Langley, studied the problem and concluded that the divergences occurred when the C-term of the stability quartic became negative and they developed a simplified form of the C-term and called it \( C_{n\beta,\text{dyn}} \), or the dynamic directional-stability parameter. The derivation of this parameter is given in the appendix.

The term \( C_{n\beta,\text{dyn}} \) seemed to correlate reasonably well with the directional divergence characteristics observed with configurations A, B, and C, and subsequent dynamic models; but at that time there were some unexplained exceptions. Because of the beginning of the air-launched missile era when fighters were not going to be maneuvered to high angles of attack, no summation of the experience with directional divergence and the correlation with \( C_{n\beta,\text{dyn}} \) was ever made, even though most of the experience was gained 10 to 15 years ago.

**CORRELATION OF \( C_{n\beta,\text{dyn}} \) WITH DIRECTIONAL DIVERGENCE**

A summary of the divergence characteristics of the configurations discussed in this paper is presented in table I along with an indication as to how well the directional divergence parameter correlated with the actual divergence characteristics. The correlations are rated as good, fair, and poor. The rating of good was assigned to configurations for which \( C_{n\beta,\text{dyn}} \) correctly indicated no divergence or correctly indicated a divergence and the angle of attack at which it occurred. Table I shows that the correlation was good in nearly two-thirds of the cases shown. This shows that \( C_{n\beta,\text{dyn}} \) can be a useful tool in predicting the occurrence of directional divergence; and, since the aerodynamic terms in the expression \( C_{n\beta,\text{dyn}} \) can be measured during static-force tests, it is relatively easy to get an indication of whether or not the airplane might experience a directional divergence. However, to determine the maximum usefulness of \( C_{n\beta,\text{dyn}} \), the cases with fair or poor correlation must be examined to study the limitations of the parameter \( C_{n\beta,\text{dyn}} \) in predicting directional divergence. The fair and poor ratings are used to designate configurations for which \( C_{n\beta,\text{dyn}} \) either fails to predict accurately the angle of attack at which a divergence occurs or fails to predict a divergence altogether.

The ability of \( C_{n\beta,\text{dyn}} \) to predict directional divergence accurately can be affected in several ways.
For example, included in the fair rating are configurations J and N (ref. 6 and unpublished data) for which \( C_{n_\beta,\text{dyn}} \) did not become negative but for which there was a dip in the curve for \( C_{\beta_\text{dyn}} \) which approached zero at the angle where the divergence occurred. It is possible in these cases that the data points plotted to obtain the curves presented do not represent the extremes of the curves and that negative values of \( C_{n_\beta,\text{dyn}} \) exist between two of the points that were plotted. Another possibility deals with the terms that were neglected in reducing the C-coefficient of the lateral equation of motion to \( C_{n_\beta,\text{dyn}} \). It is possible that for these configurations the values of these terms are large enough to cause the C-coefficient (for which \( C_{n_\beta,\text{dyn}} \) is an approximation) to become negative at points where \( C_{n_\beta,\text{dyn}} \) approaches zero.

Another factor which affects \( C_{n_\beta,\text{dyn}} \) is the use of static data which do not accurately match flight conditions in calculating \( C_{n_\beta,\text{dyn}} \). Two conditions which may not be matched are control deflections and power. In some cases these parameters can have marked effects on the static lateral-stability parameters \( C_{n_\beta} \) and \( C_{l_\beta} \).

Another reason for the inability to predict a directional divergence can be seen by examining the curves for \( C_n \) and \( C_l \) plotted against \( \beta \). In calculating \( C_{n_\beta,\text{dyn}} \), the curves for \( C_n \) and \( C_l \) against \( \beta \) are assumed to be linear. This assumption is not always true, especially at high angles of attack. An example of nonlinearity is seen in the case of configuration B (ref. 3). The curves for \( C_n \) and \( C_l \) against \( \beta \) for the higher angles of attack are shown in figure 7(c). These data show that for \( \beta = \pm 2^\circ \) and \( \beta = \pm 5^\circ \), \( C_{l_\beta} \) remains negative throughout the angle-of-attack range and \( C_{n_\beta} \) remains positive up to an angle of attack of about \( 25^\circ \), thereby resulting in a curve for \( C_{n_\beta,\text{dyn}} \) that dips at an angle of attack of \( 25^\circ \) but does not become negative. However, for \( \beta = \pm 10^\circ \), \( C_{l_\beta} \) becomes positive at an angle of attack of about \( 25^\circ \) and \( C_{n_\beta} \) becomes negative at an angle of attack of about \( 22^\circ \), thereby resulting in a negative \( C_{n_\beta,\text{dyn}} \) above an angle of attack of \( 23^\circ \). This indicates that both \( C_{n_\beta} \) and \( C_{l_\beta} \) are nonlinear between \( \beta = \pm 5^\circ \) and \( \beta = \pm 10^\circ \). Free-flight model tests showed that this configuration diverged at an angle of attack of about \( 25^\circ \).

The parameter \( C_{n_\beta,\text{dyn}} \) can also fail to predict a directional divergence when the divergence is caused by the controls. At high angles of attack the rudder may be placed in an area of reduced dynamic pressure in the wake of the wing, thereby resulting in a loss of control power. At the same time, deflection of ailerons at high angles of attack often results in large adverse yawing moments. If these adverse moments become large enough, they may overpower the stability of the aircraft, thereby resulting in a divergence while \( C_{n_\beta,\text{dyn}} \) remains positive. This type of divergence is more fully discussed in reference 7.
METHODS FOR ELIMINATING DIRECTIONAL DIVERGENCE

Since a directional divergence is a very undesirable characteristic for any aircraft, many tests have been made in an effort to determine airframe modifications which would eliminate the divergence. The results presented in table I (refs. 3 to 6 and 8 to 14) show that changes in the airplane configuration can significantly change the airplane's divergence characteristics. In this section the effects of certain airframe modifications on $C_{n\beta}$, $C_{l\beta}$, and consequently on $C_{n\beta,dyn}$ are discussed. The effect of a given modification is shown to vary from aircraft to aircraft, and therefore no general conclusions can be drawn as to the effect of a particular modification.

Increased Vertical-Tail Size

Since a directional divergence is caused by a loss in directional stability, the most obvious airframe modification to improve directional stability would seem to be an increase in the vertical-tail area. In most cases, however, the loss in directional stability is caused by the vertical tail becoming ineffective at high angles of attack because it is in the low-velocity stalled wake of the wing or because it is in a region of adverse sidewash which can even cause the tail to be destabilizing. Under such conditions, increasing the tail area might be destabilizing or at best provide little increase in stability. An example of the effect of increasing the vertical-tail size for configuration C (ref. 4) is shown in figure 8(b). The data show the expected increase in $C_{n\beta}$ and $C_{l\beta}$ in the lower angle-of-attack range, but there is little effect on the angle of attack at which the derivatives go to zero. Free-flight model tests also showed no difference in the angle of attack at which the divergence occurred with or without the vertical-tail extension. The data of figure 12(b) show the effect of doubling the vertical-tail area of configuration G (ref. 8). These data also show the expected increase in $C_{n\beta}$ and $C_{l\beta}$ at low angles of attack with the larger vertical tail, but little improvement in the high-angle-of-attack characteristics. Free-flight model tests showed an increase of $3^\circ$ in the divergence angle for the modified configuration. The data of figure 15(c) show the directional-stability characteristics of configuration J with the short nose (ref. 2) with three different vertical tails. The data show that changes in vertical tail have little effect on $C_{n\beta}$ in the high-angle-of-attack range. Free-flight model tests confirm the ineffectiveness of vertical-tail modifications on this configuration in increasing the angle of attack at which the model diverged.

These examples show that increases in vertical-tail area are relatively ineffective in improving the high-angle-of-attack characteristics of the particular configurations studied. It should be pointed out, however, that increased vertical-tail size might be beneficial for other configurations and should be considered before eliminating such a modification as a possible solution to high-angle-of-attack directional-stability deficiencies.
Leading-Edge Slats

One of the most effective means for delaying or eliminating the directional divergence seems to be the leading-edge slat. Force test data show that leading-edge slats result in increases in both $C_{n\beta}$ and $C_{l\beta}$ (with a corresponding increase in $C_{n\beta,dyn}$), especially in the high-angle-of-attack range. This increase is illustrated in figure 8(b) for configuration C (ref. 4). Free-flight model tests of configuration C showed that leading-edge slats eliminated the directional divergence. Configuration E (fig. 10(b)) shows less of an increase in $C_{n\beta}$, $C_{l\beta}$, and $C_{n\beta,dyn}$ with leading-edge slats than did configuration C, but note that this configuration did not have a divergence problem. Another outstanding example of the effect of leading-edge slats on the high-angle-of-attack characteristics is shown in figure 15(b) for configuration J (ref. 6). The effectiveness of slats in extending the angle of attack of divergence for this configuration has been verified on both free-flight models and flight test aircraft. Both tests showed a 6° increase in the angle of attack at which divergence occurred.

The data presented in figure 21 for configuration P (ref. 9) show the effect of leading-edge slats for two wing sweeps. With a sweep angle of 20° the leading-edge slats produce a large increase in $C_{n\beta}$ and $C_{l\beta}$, but for 72° sweep, $C_{n\beta}$ is decreased and $C_{l\beta}$ is only slightly improved. The effectiveness of the slats seems to be limited by sweep angle.

Although it is not documented in the present paper, experience has shown that leading-edge flaps have effects similar to those of leading-edge slats.

CONCLUSIONS

The present summary of some of the existing data on the directional divergence of high-performance jet airplanes indicates the following:

1. Most high-performance jet aircraft exhibit the directional divergence characteristics.

2. The dynamic directional-stability parameter $C_{n\beta,dyn}$ predicts directional divergence fairly well.

3. Correlation of directional divergence and $C_{n\beta,dyn}$ can be improved by carefully selecting data which represent flight conditions and by accounting for nonlinearity in the curves for yawing moment and rolling moment against angle of sideslip.

4. In some cases a reduction in $C_{l\beta,dyn}$ at high angles of attack to a near zero value may indicate a directional divergence.
5. For aircraft with moderately swept wings, leading-edge slats seem to be the most effective airframe modification for reducing or eliminating the directional divergence potential of the aircraft.

Hampton, Va., October 6, 1972.
APPENDIX

DEVELOPMENT OF $C_{n\beta,\text{dyn}}$

The lateral open-loop (no pilot) flight motions are determined by the equation

$$A\lambda^4 + B\lambda^3 + C\lambda^2 + D\lambda + E = 0$$

An aircraft becomes unstable and divergence will occur when one or more of the roots of this equation becomes positive. This equation will have unstable roots if any of the coefficients or if the combination of coefficients $BCD - AD^2 - B^2E$ (Routh's discriminant) becomes negative. Experience has shown directional divergence usually occurs when the C-coefficient becomes negative. The nondimensional form of the equation for the C-coefficient is (ref. 2)

$$C = \mu_b \left( -KX_o^2 CY_r C_{n\beta} + KX_o^2 C_{n\beta} CY_{\beta} + 4\mu_b KX_o^2 C_{n\beta} \cos \alpha ight.$$ 

$$\left. + KZ_o^2 C_{\ell\beta} CY_{\beta} - KZ_o^2 C_{\ell\beta} CY_{\alpha} - 4\mu_b KZ_o^2 C_{\ell\beta} \sin \alpha ight)$$ 

$$\left. + \frac{1}{2} C_{n\beta} C_{\ell\beta} - \frac{1}{2} C_{n\beta} C_{\ell\alpha} \right)$$

By using the definitions

$$\mu_b = \frac{m}{\rho Sb}$$

$$KX_o^2 = \frac{I_X}{mb^2}$$

and

$$KZ_o^2 = \frac{I_Z}{mb^2}$$

and rearranging the terms, the C-coefficient can be reduced to the form

$$C = KCR$$

where $K = \frac{4mI_X}{\rho^2 S^2 b^4}$ is a constant for a given configuration. A change in the sign of the C-coefficient is indicated by a change in the sign of $CR$. This reduced form of the C-coefficient is found by the equation
This equation shows that most of the terms are the product of two derivatives. These derivatives are usually $<<1$; therefore the products of these derivatives are assumed to be small compared to the other terms. Terms involving products of derivatives are dropped from the equations, thereby yielding the equation

$$C_R = C_{n\beta}(\cos \alpha - \frac{\rho S_b}{4m} C_{Yr}) - \frac{I_Z}{I_X} C_{\ell\beta}(\sin \alpha + \frac{\rho S_b}{4m} C_{Yp})$$

$$+ \frac{\rho S_b}{4I_X} C_{\ell\rho} \left( \frac{b^2}{2} C_{n_r} + \frac{I_Z}{m} C_{Y\beta} \right) + \frac{\rho S_b}{4} \left( \frac{1}{m} C_{n_r} C_{Y\beta} - \frac{b^2}{2I_X} C_{\ell_r} C_{n_p} \right)$$

This last assumption can be shown to have little effect on the results. Calculations have been made for two different configurations to compare the values of $C_R$, $C_R'$, and $C_{n\beta,\text{dyn}}$, that is, to illustrate the effect of the simplifications. The calculations were done in terms of per radian to fit the equation for $C$. The results of these calculations are presented in figure 23. These results show that $C_{n\beta,\text{dyn}}$ is a good representation of $C_R$.

Figure 9.- Concluded.
Figure 10.- Longitudinal and lateral characteristics of configuration E (unpublished data).
(b) Lateral characteristics. $\beta = \pm 5^\circ$.

Figure 10.- Concluded.
(a) Longitudinal characteristics.

Figure 11. - Longitudinal and lateral characteristics of configuration F (unpublished data).
(b) Lateral characteristics. \( \beta = \pm 5^\circ \).

Figure 11.- Concluded.
Figure 12. - Longitudinal and lateral characteristics of configuration G (ref. 8).
(b) Lateral characteristics. \( \beta = \pm 5^\circ \).

Figure 12.- Concluded.
(a) Longitudinal characteristics.

Figure 13.- Longitudinal and lateral characteristics of configuration H (ref. 10).
(b) Lateral characteristics. $\beta = \pm 5^\circ$.

Figure 13. - Concluded.
(a) Longitudinal characteristics.

Figure 14.- Longitudinal and lateral characteristics of configuration I
(ref. 11 and unpublished data).
(b) Lateral characteristics.

Figure 14.- Concluded.
Figure 15. Longitudinal characteristics of configuration J (refs. 2 and 6).

(a) Longitudinal characteristics.
(b) Lateral characteristics. Long nose. $\beta = \pm 5^\circ$.

Figure 15.- Continued.
100% increase in area
100% increase in aspect ratio
Basic vertical tail

(c) Variation of $C_{n\beta}$ with vertical-tail size. Short nose. $\beta = \pm 5^\circ$.

Figure 15.- Concluded.
Figure 16. - Longitudinal and lateral characteristics of configuration K (unpublished data).
(b) Lateral characteristics. $\beta = \pm 5^0$.

Figure 16.- Concluded.
(a) Longitudinal characteristics.

Figure 17.- Longitudinal and lateral characteristics of configuration L (unpublished data).
(b) Lateral characteristics. $\beta = \pm 5^\circ$.

Figure 17.- Concluded.
Figure 18.- Longitudinal and lateral characteristics of configuration M (ref. 12).
(b) Lateral characteristics. $\beta = \pm 5^\circ$.

Figure 18.- Concluded.
Figure 19.- Longitudinal and lateral characteristics of configuration N (unpublished data).
(b) Lateral characteristics. \( \beta = \pm 5^\circ \).

Figure 19.- Concluded.
Figure 20.- Longitudinal and lateral characteristics of configuration O (ref. 13).
(b) Lateral characteristics. $\beta = \pm 5^\circ$.

Figure 20.- Concluded.
Figure 21. Longitudinal and lateral characteristics of configuration P (ref. 9).
(b) Lateral characteristics. $\beta = \pm 5^\circ$.

Figure 21.- Continued.
Figure 21.- Concluded.
(a) Longitudinal characteristics.

Figure 22.- Longitudinal and lateral characteristics of configuration Q (ref. 14).
(b) Lateral characteristics. $\beta = \pm 5^\circ$.

Figure 22. - Concluded.
Figure 23. - Comparison of $C_R$ with $C_{R'}$ and $C_{n\beta,\text{dyn}}$ for two configurations.
(b) Configuration K. $\Lambda = 72.5^\circ$.

Figure 23.- Concluded.
